ANNEX 9A.1 AIR DISPERSION MODEL FOR

ATHERINOLAKKOS COMPRESSOR STATIONS

9A.1.1 INTRODUCTION

9A.1.1.1 SUMMARY

The Environmental Research Laboratory (EREL) of the National Centre for Scientific Research "Demokritos" performed the modelling study of the atmospheric dispersion of NOx, and CO concentrations from the future installation of the Compression of Natural Gas Stations, CS2 and CS2N, part of the EastMed Pipeline Project, at a southeast location of Lasithi (eastern Crete).

The study was carried out for ASPROFOS Engineering S.A. by the following EREL personnel:

- Vlachogianni Diamando, M.Sc., Ph.D
- Sfetsos Athanasios., Ph.D
- Gounaris Nikolaos., M.Sc.
- Emmanouil George, PhD.
- Karozis Stelios, M.Sc., Ph.D

9A.1.1.2 AIM OF THE REPORT

The scope of this study is to investigate the impact of the dispersion of Nitrogen Oxides (NOx) and Carbon Monoxide (CO) on the air quality generated by the future installation of the gas Compression Stations (CS2 and CS2N), at the south-eastern near coast corner of Lasithi, (regional unit of Crete, Greece), aimed at providing additional compression required, in the Natural Gas transmission system of the EastMed pipeline. During the operation of the onshore installation of the pipeline, pollutant gases are emitted to the atmosphere as a result of the combustion of natural gas in the compression station through Gas Turbines (GT) according to the standard of the European Association for the Streamlining of Energy Exchange – gas (EASEE-gas). Consequently, emissions of particulate matter (PM) and sulfur dioxide (SO₂) are negligible. According to the European Best available techniques Reference document (BREFs) developed under the IPPC Directive for large combustion installations, CO and NOx are the only gas pollutants emitted that should be taken into account in air dispersion modelling studies.

In the current modelling study, the 3-dimensional computer modelling tools were used with appropriate methodology² developed by the Environmental Research Laboratory (EREL) of the NCSR "Demokritos". The position and geometry of data on stacks, emission rates of NOx and CO were provided to EREL by Asprofos S.A. based on construction information.

The meteorological data for the area of interest were retrieved by EREL. The data related to the topography of the area were extracted from the Geographic Information System (ARC GIS) available at EREL. The basic computational and analysis steps followed are listed below:

- Processing of the available data, preparation of the input files for the dispersion model regarding the topography (ARC.GIS) and the meteorology of the area.
- Meteorological computational calculations to obtain the characteristic weather types of the area of interest and the respective 3-Dimensional meteorological fields (WRF model).
- Modelling calculations of the atmospheric dispersion of the emissions of NOx and CO from the gas compression stations (HYSPLIT model).
- Analysis and evaluation of the model results on the near ground distribution of the NOx and CO concentrations.
- Modelled near ground concentrations of the pollutants were compared against European air quality standards (2008/50/EC), adopted by Greek legislation, considering ambient background levels and potential receivers (populated places).

9A.1.2 PREPARATION OF THE INPUT DATA

This part involves the preparation of the input data files for the atmospheric dispersion model. For the specific study, the necessary data include the topography and meteorological fields of the area of interest.

9A.1.2.1 TOPOGRAPHY AND MODELLING DOMAIN

The geographical coordinates of the emission sources of the gas compression stations CS2 and CS2N of natural gas at the location of Lasithi (regional unit of eastern Crete) on Greek Geodetic Reference System GGRS87 (X,Y) and latitude /longitude are shown on Table A1- 1.

Prepared by Demokritos on behalf of ASPROFOS, 2022.

The computational domain extent was set to 40 x 40 km² to include as many as possible neighbouring urban areas of the eastern part of the Lasithi regional unit (see Figure A1- 1). The topography of the area includes two major mountainous areas (~1500 m) that smooth down to low levels towards the coasts.

9A.1.2.2 METEOROLOGY AND CHARACTERISTIC WEATHER TYPES

The atmospheric dispersion models use as input data meteorological variables such as wind speed and wind direction, temperature, category of atmospheric stability, mixing layer height etc. The more complex models (like the one used in this study named HYSPLIT) use 3-dimensional meteorological fields as input. The discretised meteorological fields are calculated by prognostic and/or diagnostic models.

For the current study, meteorological data (vertical distribution of wind speed and direction, temperature, mixing layer height, humidity, precipitation, cloud cover etc) were extracted from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-5 climate re-analysis dataset, (<u>https://confluence.ecmwf.int/display/CKB/ERA5%3A+data+documentation</u>), available at 3-hourly intervals.

9A.1.2.2.1 Characteristic Weather Types over the study area

To calculate the average levels and the maximum values of the pollutant concentrations from a future installation in the atmosphere on an annual, daily and hourly basis, the procedure of identifying the typical meteorological conditions or else characteristic weather types (CWT) of the area of interest was followed. The prevailing meteorological conditions or in other words characteristic weather types were obtained using the methodology of Sfetsos et al. (2005)³. The specific methodology was applied on ERA5 reanalysis data of large scale, as referenced above, covering a period of eleven years (2010-2020). The analysis revealed the prevailing weather conditions in the defined computational domain and the corresponding frequency of occurrence (in percentage) per year. Each weather condition was assigned a characteristic or else typical day (24-hour). The results showed that the area of study is characterised by twelve (12) in total weather types (see Table A1- 2). Table A1- 3, summarises the meteorological conditions from the global reanalysis model, which characterise each typical weather day of the region.

		PAGE :	15 OF 33	

wind speed per direction. It can be concluded that the dominant direction at this location is the South-East (SW). The winds from the other directions have much lower frequency of occurrence.

9A.1.2.2.2 Weather conditions description

The description of the weather conditions prevailing during each characteristic weather type of Table A1- 2 (CWT) is provided below.

• CWT1

A deep low barometric atmospheric system is moving eastwards, north of Crete, causing cloudiness and rain by night, at the Lasithi region during this autumn type. The winds are blowing from west directions, moderate to strong and the temperature reaches 21-23 degrees Celsius at noon (in the southern areas).

• CWT2

Smooth barometric field of relatively high pressures is covering the area, with sunny weather and only local clouds over the Lasithi region during this autumn type. The winds blow northwesterlies, strong to near gale and the temperature reaches 22-24 degrees Celsius at noon.

• CWT3

Smooth barometric field of relatively high pressures is covering the area of interest, with fine spring weather. The winds blow north-westerlies moderate to strong and the temperature up to 24 degrees Celsius at noon.

• CWT4

A relatively low-pressure barometric field is affecting the weather of the area with fair conditions and few clouds over the area of Crete during this spring type. The winds are north-westerlies strong and the temperature reaches 18-20 degrees Celsius at noon.

• CWT5

Smooth barometric field of relatively low pressures is covering the area with scattered clouds during this spring type. The winds blow from southwest directions with moderate speeds and the temperature rises to 20-22 Celsius degrees.

• CWT6

A smooth barometric field is resulting to fine summer weather over the area of interest. The winds blow from northwest with strong intensity and the temperature is reaching 29-31 degrees Celsius over the southern coasts.

• CWT7

iGI Poseidon	EASTMED PIPELINE PROJECT	ERM	Asprofos
	EastMed Greek Section – Environmental and	REE-ESIA- 1ex9A1	
	Social Impact Assessment	REV. :	00
		PAGE :	16 OF 33

Relatively low pressures between Crete and Cyprus are combined with high pressures over north-western Greece, resulting to fine weather conditions over Lasithi region, with light to moderate north-westerly winds and temperature of 30-32 degrees Celsius, during this summer type.

• CWT8

Relatively low pressures over the central Aegean Sea are resulting to temporary cloudiness over Lasithi region and short rains in the afternoon over mountainous areas. The winds blow from southwest directions strong, veering in the afternoon to northerlies strong, while the temperature reaches 25-27 degrees Celsius, during this summer type.

• CWT9

Relatively low pressures between Crete and Cyprus are combined with high pressures over central Mediterranean Sea, resulting to fine weather conditions over Crete, with strong to near gale north-westerly winds and temperature of 28-30 degrees Celsius, during this summer type.

• CWT10

Relatively low pressures over Cyprus are combined with high pressures over north-western Greece, resulting to fine weather conditions over the study area, with strong to near gale north-westerly winds and temperature of 32-34 degrees Celsius, during this summer type.

• CWT11

An extensive low-pressure system over the Italian peninsula is moving slowly eastwards, resulting to gradual cloudiness over Crete, gradual intense of the south-easterly winds and maximum temperature of 13-15 degrees Celsius over the southern coastal areas, during this winter type.

• CWT12

Relatively high pressures are covering the Greek area, resulting to good weather over the study area. The winds blow from northwest with strong intensity, veering in the afternoon to westerlies weakening particularly in late hours, while the temperature rises to 16-18 degrees Celsius, during this winter type.

9A.1.2.2.3 Atmospheric model WRF

The prognostic meteorological model Weather Research Forecasting (WRF-ARW) version 3.6.1 (Skamarock et al., 2008)⁴ was set-up and used for the calculation of the 3-dimensional meteorological fields. The WRF model calculated the 3-dimensional meteorological fields of the region of interest, in

⁴ Skamarock, W. C., J. B. Klemp, J. Dudhia, D. O. Gill, D. M. Barker, M. G. Duda, X.-Y. Huang, W. Wang, and J. G. Powers, 2008: A description of the Advanced Research WRF version 3. NCAR Technical Note 475, http://www.mmm.ucar.edu/wrf/users/docs/arw v3.pdf.

a domain of 40 ×40 km² (Figure A1- 1) and horizontal and temporal resolution of 1×1 km² and 1hour, respectively. The ERA-5 data for the determined characteristic weather days were used as initial and boundary conditions to the meteorological model (WRF). The model simulations were performed for the 12 characteristic weather days (CWT).

As an example of the WRF results, Figure A1- 3, Figure A1- 4 display examples of the WRF calculated 3-dimensional temperature and wind fields for CWT1 (autumn), CWT4 (spring), CWT6(summer) and CWT11 (winter) at 12:00 hr and 24:00 hr. The calculated meteorological fields were consequently used as input to the dispersion model

9A.1.2.3 SIMULATION OF THE DISPERSION OF THE POLLUTANTS

This chapter presents the preparation of the input data for the atmospheric dispersion model HYSPLIT (Hybrid Single Particle Lagrangian Integrated Trajectory Model) used in the present study.

9A.1.2.3.1 The Dispersion Model

The HYSPLIT model is the newest version of a complete system for computing simple air parcel trajectories to complex dispersion and deposition simulations. As a result of a joint effort between NOAA and Australia's Bureau of Meteorology, the model has been used for several applications (<u>https://ready.arl.noaa.gov/HYSPLIT.php</u>). The Air Resources Laboratory's HYbrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model is a complete system for computing both simple air parcel trajectories and complex dispersion and deposition simulations. The model calculation method is a hybrid between the Lagrangian approach, which uses a moving frame of reference as the air parcels move from their initial location, and the Eulerian approach, which uses a fixed three-dimensional grid as a frame of reference. In the model, advection and diffusion calculations are made in a Lagrangian framework following the transport of the air parcel, while pollutant concentrations are calculated on a fixed grid. The model is designed to support a wide range of simulations related to the atmospheric transport and dispersion of pollutants and hazardous materials, as well as the deposition of these materials onto the Earth's surface.

9A.1.2.3.1.1 Data of the pollutant emissions from CS2 and CS2N

Each compression station is designed to comprise three stacks– Gas Turbines of 25.2 MW each (in ISO conditions), 6 in total and identical in characteristics and emission data. The spare turbine of CS2 was not included in the dispersion study. The computational study simulated the maximum operation of the CSs for in total 8,585 hours.

Table A1- 4 presents the data on the geometric characteristics of the stacks and the gas flow properties of the emission source. Table A1- 5 provides the emission values of the pollutants.

9A.1.3 ATMOSPHERIC DISPERSION CALCULATIONS

This section focuses on the analysis of the HYSPLIT model results of the concentration values of NO_x , and CO from CS2 and CS2N.

The concentrations of NO_x were calculated on an hourly and annual basis to compare the modelled calculated results with the respective air quality limits as set by the legislation in force (MD 14122/549/E.103/2011 "Measures to improve air quality in compliance with the provisions of Directive 2008/50/EC "on the air quality and cleaner air for Europe" the European Parliament and Council of the European Union of 21 May 2008"). According to the current directive, the air quality limit for NO₂ for averaging period of 1 hour is set at 200 μ g/m³, not to be exceeded more than 18 times a calendar. On an annual average basis, the respective limit is 40 μ g/m³. The CO values were calculated as maximum daily 8 hour running mean concentrations for comparison with the respective air quality limit of 10 mg/m³ (Directive 2008/50/EC).

The modelling approach was performed without the inclusion of the photochemical reactions which could reduce the concentrations of NO_x and CO in the atmosphere for the reason of obtaining the maximum possible values in the domain. Moreover, detailed data on the compounds from high resolution inventories would be needed for a photochemical model, which were not available. Special attention was given to the populated areas around the location of the gas compression stations.

A field survey campaign was carried out during the period of 26/05/2021 - 30/06/2021 to investigate the ambient air quality conditions in the area of interest. Details about the field sampling can be found in the corresponding section of the report.

Figure A1- 5 shows the location of the sampling sites and Table A1- 6 summarises the results from the field measurements. The measured data represent mean hourly concentrations of the period of approximately one month during the summer season. The measurements showed that the hourly average background concentrations of both pollutants of interest were of significant low values compared to those found in more heavily populated areas of the country. In particular, the CO ambient concentrations were lower than the detection limit (0.6 mg/m³) of the measuring device and analytical method except for the locations of DEH, where the power plant installation is, and for the residential area Asprolithos, which is in close distance from the power plant. In addition, the ambient NOx concentrations were measured to be very low of an average value of 1.94 μ g/m³ while in the majority of the sampling locations, the concentrations remained below the detection limit 0.7 μ g/m³. Hence, the ambient concentrations of the CO and NOx were not considered in the modelling study.

9A.1.3.1 Pollutant concentrations from CS2 and CS2N

Table A1-7 presents the maximum hourly average concentration of NO_x determined for each characteristic weather type. It can be observed that the **maximum hourly average values of NO_x** concentrations from the CC2 and CS2N do not exceed the limit of 200 μ g/m³ during any characteristic weather type. In fact, the maximum hourly average NO_x concentrations remain low and well below the air quality limit. The maximum hourly average concentration of NO_x of 26.11 μ g/m³ was found during CWT3. This value occurred for 1 hour only during the CWT3 in rather stable atmospheric conditions.

Table A1- 8 shows the maximum hourly and annual average concentrations of NO_x as well as the maximum 8-hour running mean value of CO calculated in the domain, for direct comparison with the legislative limits. It can be deduced that these maximum pollutant values are very low compared to the air quality limits (2008/50/EC).

Table A1- 9 summarizes the maximum hourly average and annual NO_x concentrations as well as the CO maximum 8-hour running mean values calculated by the dispersion model over all the residential areas of the domain at a maximum distance of ~25 km from the centroid of the industrial field. The concentrations of the pollutants are negligible above the residential areas compared to the corresponding air-quality limits.

Prepared by Demokritos on behalf of ASPROFOS, 2022.

Figure A1- 6 and Figure A1- 7 depict the maximum hourly and annual average concentrations of NO_x from the gas compression stations, calculated by the model taking into account the 12 characteristic weather types of the region and their frequency of occurrence within a typical year (see Table A1- 2). It can be deduced, that no exceedances of the NO_x and CO respective air quality limits occur over the populated areas within an approximate distance of 20 km from GS2 and GS2N. In fact, the maximum hourly (for each CWT) and annual NO_x concentrations are found to be very low compared to the legislative limits (2008/50/EC), (see Table A1- 8, Figure A1- 6 and Figure A1- 7).

In particular, the maximum hourly average concentration of NO_x of 8.59 $\mu g/m^3$ is calculated over the residential area of Goudouras, which is at the closest distance from the gas stations (air quality limit

IGI Poseidon	EASTMED PIPELINE PROJECT	ASTMED PIPELINE PROJECT

		PAGE :	28 OF 33		

200 µg/m3) (see, Table A1- 9). The maximum hourly NO_x concentrations, dispersed to the more distant populated areas of the domain, are not found to exceed the value of 5.0 $\mu g/m^3$, while over most residential sites the concentrations are equal to zero (Figure A1- 6). The maximum annual NO_x concentration of 2.83 $\mu g/m^3$ calculated in the area is also very low compared to the respective air quality limit of 40 µg/m³ (see Figure A1- 7, Table A1- 8).

A similar conclusion is drawn for the maximum 8-hour running mean CO concentrations, which are found to be negligible compared to the air quality limit (10000 μ g/m³, 2008/50/EC). The maximum calculated CO concentration is equal to 27.48 μ g/m³ during the CWT12 (winter period) (Figure A1-8). The maximum CO concentration calculated over the residential area of Goudouras is equal to 12.99 μ g/m³ (Table A1- 9). Overall, the maximum CO concentrations do not exceed the air quality limit anywhere in the domain and during any characteristic weather type.

It can be concluded that the modelled NO_x and CO concentrations from both compression stations (CS2 and CS2N), at the location of Lasithi, emitted from six identical gas turbines are very low and insignificant compared to the air quality limits of the legislation in force.

9A.1.4 SUMMARY – CONCLUSIONS

The aim of the current study was to investigate the dispersion of NO_x and CO emissions from the future gas compressor stations CS2 and CS2N in the Lasithi area (Crete). The study was performed with the 3-dimensional computer modelling tools and appropriate methodology used and developed

Figure A1- 8 Modelled near surface calculated 8-hour running mean concentration values of CO (μg/m3) CS2 & CS2N for the 12 CWT. Red triangle indicates the centroid of the industrial field. Air quality limit for 8-hour concentration: 10000 (μg/m3).

by the Environmental Research Laboratory (EREL) of the NCSR "Demokritos". The contribution of the measured ambient concentrations was also taken into account in the dispersion simulation. The dimensions of the modelling domain were large enough to include sufficiently the residential areas within a reasonable distance from the gas compression stations. Thus, the domain size for the modelling calculations was set to $40 \times 40 \text{ km}^2$. For the modelling needs, the initial meteorological data were retrieved from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-5 climate *high-resolution reanalysis* of 3-hours, covering in total eleven (11) years. To calculate the average levels and the maximum values of the pollutant concentrations in the atmosphere from the future installations on an annual, daily and hourly basis, the procedure of identifying the characteristic weather types (CWT) of the area of interest was followed. The analysis revealed twelve (12) characteristic weather types (CWT) in the domain. Using these data as input to the WRF atmospheric model, the 3-d meteorological fields were calculated with a horizontal and temporal resolution of $1 \times 1 \text{ km}^2$ and 1-hour, respectively.

For the air dispersion calculations, the atmospheric dispersion model HYSPLIT (Hybrid Single Particle Lagrangian Integrated Trajectory Model) was employed. The simulations were carried out with a 1-hour resolution. The modelling was based on the technical information available at the stage of the study by ASPROFOS SA. The ambient concentrations of NO_x and CO were not considered in the modelling study as the field measurements in the area surrounding the industrial field were found to be low and negligible for a meaningful assessment.

The near-surface hourly average and annual NO_x concentrations as well as the 8-hour running mean CO values were calculated in order to be comparable to the respective air quality limits as set by the legislation in force (MD 14122/549/E.103/2011 "Measures to improve air quality in compliance with the provisions of Directive 2008/50/EC "on the air quality and cleaner air for Europe" the European Parliament and Council of the European Union of 21 May 2008").

Overall, the hourly mean and annual NO_x concentrations were calculated to be lower than the air quality limits everywhere in the domain and during all CWTs. Similarly, the CO concentrations were calculated to be negligible compared to the air quality legislative limit. The maximum pollutant concentrations were found to occur during specific characteristic weather types (CWT3 and CWT12) due to conditions that resulted from the combination of atmospheric stability and rather weak wind fields, in late night hours. It must also be emphasised that no exceedances of the NO₂ and CO respective air quality limits were found over the populated settlements within a distance of approximately 25 km due to the emissions from the gas compressor stations. Conclusively, the modelling study yielded the following results:

• The maximum mean hourly NO_x concentration was found to be equal to ~13% of the air quality limit 200 μ g/m³ (during CWT3, spring period).

iGI Poseidon	EASTMED PIPELINE PROJECT	ERM	Asprofos
	EastMed Greek Section – Environmental and	DOCNo: PERM-GREE-ESIA- A09_0003_0_Annex9A1

		PAGE :	33 OF 33

- The maximum annual NO_x concentration was found to be equal to 7% of the air quality limit 40 μ g/m³.
- The maximum 8-hour running mean CO concentration was found to be equal to 0.27% of the air quality limit of 10000 μ g/m³ (during CWT12, winter period).
